Introduction

The ability of palladium metal complexes to be creatively designed has led to increased versatility and selectivity as catalysts and permitted relatively mild reaction conditions. However, this has also led to an increased usage in the development of Active Pharmaceutical Ingredients (APIs). Palladium byproducts as a result of this synthesis are often difficult to remove and toxic to ingest. Therefore, it is of vital importance to efficiently and accurately identify the residual palladium catalyst in synthetic API compounds intended for use in biological studies, especially human consumption.

One of the more innovative and successful approaches to sense palladium is through the installation of allyl groups on phenolic fluorophores. The removal of this allyl group through a palladium-catalyzed substitution reaction, called the Tsuji-Trost reaction, results in a fluorescent molecule and a large increase in fluorescence as a result. In most cases, a faster rate of this deallylation reaction indicates a more useful palladium sensor.

Our goal for this project was to utilize a set of phenolic fluorophores generously given to this lab in order to test their abilities at sensing palladium at different concentrations. The initial rates of the deallylation reaction can be graphed, which would tell us at what levels of palladium the compound can be distinguished from the blank and considered an effective indicator. By using seven different concentrations of palladium, we will be able to divulge lower limits of detection for each of the novel fluorophores and determine what effects additional functional groups have on palladium sensing capabilities.

Preliminary Results

Procedure

- Prepared 10 mM solution of each compound to be tested in ~1mL DMSO
- 100 mM solutions of tri(2-furyl)phosphine (TFP) and NaBH₄
- Two cuvettes were prepared. One cuvette served as the blank with 2mL MeOH and one served as a sample with the following:
  - 1.9425 mL MeOH
  - 10 µL TFP (100 mM)
  - 25 µL NaBH₄ (100 mM)
  - 2.5 µL PM1_24A or other deallylated compound to be tested (10 mM)
  - 20 µL MeOH

Carey Eclipse Fluorimeter used to find excitation and emission wavelengths, optimal PMT and slit widths, and background fluorescence.

Serial dilution of Pd(allyl)₂Br₂ at 500 µM then 10 µM (Concentration 0); At 500 µM then 10 µM (Concentration 0) (Concentration 0). Using the the two dilutions, 1:2 dilutions were prepared down to 0.0137 µM (Concentrations 1-6).

Two runs were performed for each trial: First the Blank, 0, 1, 2; then 3, 4, 5, and 6. The compounds in previous research had better results. Still, there are some things that might be able to maximize the efficiency of the unsubstituted compounds success:

- Weaker electron withdrawing groups
- Carbonyl functional groups
- Nitro group
- Amines

The next logical step is to report the findings our contributor and determine if there are any other tests that should be done or if a new library of compounds should be used.

Analysis and Discussion

First trial of PM1_17B showed sporadic changes in background fluorescence. The instability of the compound resulted in poor results that forced us to discontinue analysis.

Future Work

The initial analysis of these compounds did not show much promise for this group of fluorescent dyes as palladium sensors. The compounds in previous research had better results. Still, there are some things that might be able to maximize the efficiency of the unsubstituted compounds success:

- Weaker electron withdrawing groups
- Carbonyl functional groups
- Nitro group
- Amines

The next logical step is to report the findings our contributor and determine if there are any other tests that should be done or if a new library of compounds should be used.
